Abstract

The mechanism of nucleation and propagation of low energy layering fracture, observed during thermo-mechanical testing of Al-2.5Mg-0.7Li alloy in as cast condition, was analyzed. Since the low energy layering fracture is affected by Li segregations and microstructural constituents’ development, solidification sequence of Al-2.5Mg-0.7Li alloy was investigated in equilibrium and non-equilibrium conditions. Results of the investigations have shown that Mg has more pronounced effect on low energy layering fracture due to reducing solubility of Li in liquid phase and $\alpha_{Al}$, maximizing precipitation of hardening (Al$_3$Li) $\delta'$ phase, ternary (Al$_4$LiMg) T phase and (Al$_8$Mg$_5$) $\beta$ phase, and reducing ductility by solid solution hardening.

Keywords: Al-Mg-Li alloy, phase precipitation, Li solubility, solidification sequence, low energy delamination fracture

INTRODUCTION

Density reduction, stiffness increase [1], increase in fracture toughness [2], fatigue crack growth resistance [3] and crack propagation behavior [4] (nucleation and growth of small [5] and long [6] cracks) as well as enhanced corrosion resistance [7] are considered to be the benefits of aluminum-magnesium-lithium (Al-Mg-Li) alloy application. The mechanical properties of Al-Mg-Li alloys are the result of microstructural constituents’ development during solidification and/or thermo-mechanical processing [8]. Microstructural constituents characteristic for Al-Mg-Li alloys are nature and volume fraction of strengthening precipitates [9], amount of coherent precipitates that alter the planar slip deformation behavior [10], content, size and distribution of coarse and angular equilibrium precipitates [9] as well as formation and widening of low precipitation frequency zone (PFZ) [1]. Microstructural constituents’ developed during solidification are influenced by chemical composition, thermodynamic parameters and processing parameters.

Each weight percent of Li added decreases the density by approximately 3 % [11] and increases Young’s modulus by 6 % [12], for the additions up to 4 wt. % [13]. However, maximum strength is obtained in the range of 1.1-1.3 wt.% Li [14]. Increasing of Li content above 1.3 wt.% will result in yield and tensile strength decrease, respectively [15]. Furthermore, according to [16, 17] alloys with Li content greater than 1 wt.% are prone to
low energy layering fracture. Layering fracture is characterized by the failure along the grain boundaries [18]. Low energy layering fracture is attributed to Li segregations at grain boundaries [18, 19], high frequency of grain boundary precipitates [20] followed by the formation of PFZ at the grain boundaries [21] and planar slip band formation [22]. The grain boundary segregation and non-uniformly distributed precipitates are result of coarse grain structure developed during solidification. Developed coarse grain structure has a preferred crystallographic orientation or texture with respect to ingot geometry. A preferred crystallographic orientation and evaluated texture cause anisotropy of mechanical properties [23]. Since the grain boundary area is small, high volume fraction of grain boundary precipitates form a continuous film. Formation of continuous film weakens grain boundaries enabling nucleation and propagation of cracks along the grain boundaries [20]. PFZ is formed during the reaction between grain boundary precipitates and pockets of bulk liquid. Widening of PFZ is a result of phase precipitation in the solid solution [24]. The low precipitation frequency increases plasticity and stress around grain boundary precipitates leading to the vacancy nucleation [25]. Additionally, the vacancy nucleation is facilitated by the planar slip bands impinging on the grain boundaries [26].

The solidification surface in the Al corner of the Al-Li-Mg system is given in Figure 1. The corresponding invariant reactions are given in Table 1.

Based on the liquids projection in the Al corner following phases are in equilibrium with the $\alpha_{\text{Al}}$ solid solution: $\text{AlLi}$ ($\delta$), $\text{Al}_2\text{LiMg}$ ($T$), $\text{Al}_{12}\text{Mg}_{17}$ ($\gamma$) and $\text{Al}_8\text{Mg}_5$ ($\beta$) (Figure 1). According to the Table 1., solidification begins with the eutectic reaction at 602°C involving primary $\alpha_{\text{Al}}$ dendrite network development and precipitation of stable $\delta$ phase (e1). Ternary $T$ phase precipitates during peritectic reaction between stable $\delta$ phase and bulk liquid phase enriched in Mg (P1). $T$ phase is the only ternary phase in this system existing in the range of 10.3 % to 11.3 % of Li and 27.1 % to 24.0 % of Mg respectively [28]. It has a complex cubic lattice and tends to precipitate at high angle grain boundaries [29]. Since stable $\delta$ phase is dissolved, precipitation of $T$ phase leads to formation of PFZ. The low precipitation frequency areas have a low crack resistance and contribute to the formation of cracks at the grain boundaries. The creep and crack resistance is additionally reduced by precipitation of $\gamma$ phase [30] (P3) and secondary eutectic $\beta$ phases [31] (e2). The additions of Li narrow the composition range of $\beta$ phase and widen homogeneity of $\gamma$ [27] phase area. Consequently, $\gamma$ phase stays in equilibrium with $\alpha_{\text{Al}}$ (P4) longer. The irregular coarse particles of $\beta$ phase precipitate at the grain boundaries as a secondary eutectic phase [27].

The solid solubility of Li and Mg in $\alpha_{\text{Al}}$ related to temperatures is given in Figure 2. The mutual solid solubility of Li and Mg in $\alpha_{\text{Al}}$ at 470°C, 430°C and 200°C is indicated in Table 2.

Mg reduces solubility of Li resulting in the formation of high volume fraction of Al-Li based precipitates, mainly $\delta$ and $T$ phase [33]. Despite precipitation of $\gamma$ and $\beta$ phase, solid solution of $\alpha_{\text{Al}}$ stays enriched in Mg (Table 2). Consequently, Mg enrichment enhances lattice of $\alpha_{\text{Al}}$ causing solid solution strengthening [34].

Thermodynamic parameters, mainly cooling rate, significantly influence solidification sequence. Equilibrium solidification of 1420 alloy, containing 5.5 % Mg and 2.0 % Li, involves
only formation of $\alpha_{Al}$ dendrite network. The $\delta$ and T phase precipitate in solid state. However, in real, non-equilibrium conditions, solidification require transformation of $\alpha_{Al}$ dendrite network and eutectic precipitation of stable $\delta$ phase [35]. Ternary T phase precipitates during peritectic reaction between stable $\delta$ phase and liquid phase. Since stable $\delta$ phase is dissolved, precipitation of T phase causes formation of low precipitation frequency areas. Since Mg reduces solubility of Li in $\alpha_{Al}$ high volume fraction of $\delta$ and T phase is expected. By the end of solidification sequence, $\alpha_{Al}$ lattice stays enhanced due to the Mg enrichment [32].

Taking into account all interactions, the possible causes of low energy layering fracture represent a synergy of Li segregations at grain boundaries, high frequency of grain boundary precipitates, formation of PFZ at the grain boundaries and planar slip band formation. Layering fracture is unlikely caused by Li segregations because of its reduced solubility in liquid phase (Table 1, point e1, e2, P1, P4) and $\alpha_{Al}$ (Table 2). Since Mg significantly reduces solubility of Li in $\alpha_{Al}$, Mg has more pronounced effect on microstructural constituents’ development and mechanical properties.

The goal of this research is to understand mechanism of layering crack formation observed during thermo-mechanical testing of Al-2.5Mg-0.7Li alloy in as cast condition. Solidification sequence under equilibrium conditions was identified using Computer Aided Thermodynamic Diagram Calculation (CALPHAD). CALPHAD enabled tracking interactions of Li and Mg with bulk $\alpha_{Al}$ as well as solidification sequence prediction and reactions in both liquid and solid state respectively. Microstructural constituents development under non-equilibrium conditions was identified using differential scanning calorimetry (DSC), metallographic analysis and X-ray diffraction (XRD).

**MATERIALS AND METHODS**

The Al-2.5Mg-0.7Li alloy was synthesized in an induction melting furnace under protective atmosphere of argon (Ar) and crucible cover. The alloy was cast into a permanent steel mold without protective atmosphere. Chemical composition of synthesized alloy was determined using ARL™ 4460 Optical Mass Spectroscope.

Application of CALPHAD enabled identification of solidification sequence under equilibrium conditions. Significant temperatures of phase transformations and precipitations were determined using DSC method. The samples were tested using heating and cooling rates of 50, 10, 2 K/min. Comparison of significant temperatures of phase transformations and precipitations with results from XRD and metallographic analysis enabled determination of solidification in non-equilibrium conditions.

Samples for metallographic analysis were prepared using grinding/polishing machine Phenix Beta Biller SAD. In order to observe grain boundaries and precipitates, samples were etched using Poulton’s, Keller’s and Weck’s etching solutions. Macrostructure was observed using stereo microscope Olympus SZ11. The Olympus GX51 inverted metallographic microscope was used to perform light microscopy. Electron microscopy was done on Tescan, Vega TS 5136 MM equipped with energy dispersive spectrometer (EDS). Since EDS does not
have a possibility for Li identification, exact prediction of present phases was done by XRD method using Philips PANalytical X'Pert PRO X-ray diffractometer.

Compression testing was conducted on GLEEBLE 1500 D machine. The sample in as cast condition was tested at room temperature. The force of 1.3 N was applied with strain rate of 230 mm/min.

RESULTS AND DISCUSSION

Phase transformation and precipitations under equilibrium conditions, determined using Thermo-Calc software support, are given in Figure 3.

According to Thermo-Calc calculations, equilibrium solidification begins with transformation of α_{Al} dendritic network at 640°C (Figure 3 b). Ternary T phase and β phase precipitate in solid solution (Figure 3 a, b). The T phase precipitates at 230°C during eutectoid reaction followed by decrease in the amount of α_{Al} (Figure 3 b). Solidification sequence, under equilibrium conditions ends with the precipitation of β phase. The β phase precipitates from bulked α_{Al}’ at 146.5°C.
The amount of components in liquid (L) phase is given in Figure 4.

The average content of Al in L phase (0.03588 mol) stays constant until the temperature of 640°C when it starts to drop rapidly. The rapid drop is caused by phase transformation resulting in dendritic network development \((α_{Al})\) (Figure 4 a). The changes in the amount of Mg (0.00103 mol) and Li (0.00101 mol) in L phase behave similarly (Figure 4 b).

The amount of components in \(α_{Al}\) is given in Figure 5 a and b.

Based on the Figure 5 a, two changes in the average amount of Al (0.03588 mol) in \(α_{Al}\) can be found. The first drop in the average amount of Al is caused by eutectoid precipitation of ternary T phase at 230°C. The second drop in average amount of Al (0.037574 mol) is a result of precipitation of \(β\) phase at 146.5°C. At the end of solidification sequence, the average amount of Al in \(α_{Al}\) is 0.03341 mol. Starting average content of Mg is 0.00103 mol and Li is 0.00101 mol in \(α_{Al}\) at 632.7°C respectively. The average amount of Li in \(α_{Al}\) is rapidly reduced during the precipitation of ternary T phase because of the Mg influence and reduced
solubility. At the end of solidification the average content of Li in $\alpha_{Al}$ is $1.04706e^{-5}$ (Figure 5 b). During precipitation of ternary T phase at 230°C the average content of Mg in $\alpha_{Al}$ decreases to $9.93495e^{-4}$. However, the pronounced change in the amount of Mg in $\alpha_{Al}$ is caused by precipitation of $\beta$ phase at 146.5°C (Figure 5 b). The average content of Mg in $\alpha_{Al}$ at the end of solidification sequence is $8.30476e^{-5}$.

The amount of components in T phase is given in Figure 6 a and b.

![Figure 6. Component ration in T phase:](image)

- a) Al
- b) Mg and Li

The average content of Al in ternary T phase grows from starting $1.32877e^{-4}$ mol at 230°C to 0.00149 mol at the end of solidification (Figure 6 a). Since Mg reduces solubility of Li in $\alpha_{Al}$, the amount of Li in T phase grows exponentially from the starting $8.27349e^{-5}$ mol until the temperature of 146.5°C (Figure 6 b) and precipitation of $\beta$ phase. The average content of Li at the end of solidification sequence is $9.3045e^{-4}$ mol. After precipitation of $\beta$ phase begins at 146.5°C, the amount of Mg in ternary T phase grows slowly from starting $3.50997e^{-5}$ to $3.94737e^{-4}$ (Figure 6 b).

The amount of components in $\beta$ phase is given in Figure 7 a and b.

![Figure 7. Component ration in $\beta$ phase:](image)

- a) Al
- b) Mg and Li
The starting average content of Al is 8.35005e-5 mol and Mg is 4.53609e-5 mol in β phase at 146.5°C respectively. At the end of solidification sequence, β phase contains in average 9.7274e-4 Al and 5.50811e-4 Mg. The average content of Li in β phase grows from starting 7.72156e-6 mol to 6.75787e-5 mol at the end of solidification sequence.

Calculation of Al-2.5Mg-0.7Li alloy under equilibrium conditions, involves only transformation of α_AL phase (Figure 5 a). Ternary T phase and β phase precipitate from the solid solution of α_AL phase (Figure 5 b). The reduced solubility of Li in α_AL phase causes precipitation of T phase leading to the significant depletion of Li from α_AL (Figure 5 b and Figure 6 b). Even due Mg is depleted from α_AL during precipitation of T phase, the amount of Mg is more significantly reduced during precipitation of β phase (Figure 5 b and Figure 6 b).

The influence of heating and cooling rates on the solidification sequence of Al-2.5Mg-0.7Li alloy is shown in Table 4.

Solidification sequence of Al-2.5Mg-0.7Li alloy under non-equilibrium conditions begins with transformation of α_AL. Reduced solubility of Li in remaining L phase, and already formed α_AL leads to eutectic reaction resulting with precipitation of metastable δ' inside the α_AL grains. Precipitation of δ' is aided by constitutional undercooling due to the Mg influence. With further temperature decrease, stable δ phase nucleates on the grain boundaries of α_AL. Stable δ phase evaluated by reaction of previously precipitated α_AL and metastable δ' phase. Dissolution of δ' phase causes formation of PFZ near the grain boundaries. Elongated ternary phase precipitates due to the reaction of Mg from bulk α_AL' and already precipitated δ' phase. Precipitation of T phase leads to the further reduction of precipitation frequency. Solidification sequence ends with precipitation of secondary eutectic β phase followed by decrease in Mg content of α_AL''.

The microstructure of Al-2.5Mg-0.7Li is given in Figure 8. The individual phases were identified using literature survey comparison.
Particles of metastable $\delta'$ are found inside the grains of $\alpha_{\text{Al}}$ (Figure 8). The metastable $\delta'$ phase is a main strengthening precipitate in Al-Mg-Li alloys. It interacts with dislocations and leads to the formation of microstructural texture [11]. Stable $\delta$ phase can be found on grain boundaries. Precipitation of stable $\delta$ phase caused formation of PFZ near the grain boundaries (Figure 8). Ternary T phase can be found on the grain boundaries as well as inside the grains. Precipitation of T phase led to the further decrease of precipitation frequency (Figure 8) near the grain boundaries. Irregular coarse particles of secondary eutectic $\beta$ phase can be found in the last solidifying areas (Figure 8).

The scanning electron image (SEI) and following mapping analysis are given in Figure 9 a and b. The positions for EDS quantitative analysis are indicated in Figure 9 a. The EDS is performed on characteristics phases at grain boundary as well as on different distances from it.

Figure 9 a shows SEI of densely distributed phases in $\alpha_{\text{Al}}$ matrix. Results of mapping analysis show significant variations in color intensity concerning Mg content (Figure 9 b). Based on
the mapping analysis, highest concentration of Mg can be found near grain boundaries. Results of additional EDS quantitative analysis are given in Table 5.

Since the measurements taken at the position 1-5 indicate the occurrence of different phases, measurements taken at the position 6 confirm the existence of residual Mg in bulk α<sub>Al</sub>.

Macrostructure of the sample’s perpendicular quarter-section before compression testing is given in Figure 10 a. Microstructure of the sample in as cast condition is given in Figure 10 b.

![Figure 10](image)

Figure 10. Sample’s quarter section perpendicular to the testing direction:
a) Macrostructure of the sample in as cast condition,
b) Microstructure of sample before compression testing, Multiple Image Alignment (MIA)

Sample exhibits typical structure for permanent mold castings. Formation of thin chill zone is followed by formation of columnar grains zone. Coarse equiaxed grains can be found in the middle of the sample (Figure 10 a).

Dendrites of α<sub>Al</sub> developing in columnar zone have preferred orientation (Figure 10 b). The α<sub>Al</sub> dendrites developing in equiaxed zone are coarse and filamentary (Figure 10 b).
Macrostructure of the sample after compression testing is given in Figure 11.

The compression testing led to the significant texture development, as shown in Figure 11 a. Macrostructure of the surface parallel to the testing direction reveals significant cracking (Figure 11 b). The crack nucleated at the surface of the sample and propagated towards the center.
MIA of the area of the defects is given in Figure 12.

![Figure 12. MIA of the affected area in: a) As polished condition, b) After etching with Poulton’s etching solution, c) After etching with Wecks’s etching solution](image_url)

The cracks nucleate at the surface defect and propagate towards the center of the sample, as shown in Figure 12 a. Etching to reveal the grain structure enabled identification of the defect as a failure along the grain boundaries (Figure 12 b). Result of color etching, given in Figure 12 c, indicated significant texture development in the area of the interest.
CONCLUSIONS

The mechanism of nucleation and propagation of low energy layering fracture, observed during thermo-mechanical testing of Al-2.5Mg-0.7Li alloy in as cast condition, was analyzed. Low energy layering fracture is influenced by Li segregations and microstructural constituents’ development. Both, changes in the amount of components (Al, Li and Mg) in individual phases and solidification sequence of Al-2.5Mg-0.7Li alloy were investigated in equilibrium and non-equilibrium conditions.

Solidification sequence in equilibrium conditions involves transformation of $\alpha_{\text{Al}}$ followed by the precipitation of ternary T phase and $\beta$ phase. The amount of Li in $\alpha_{\text{Al}}$ is rapidly reduced during the precipitation of ternary T phase due to the reduced solubility and Mg influence.

Changes in solidification sequence under non-equilibrium conditions are a result of reduced solubility of Li in L phase and $\alpha_{\text{Al}}$. Solidification sequence begins with transformation of $\alpha_{\text{Al}}$ dendritic network. Reduced solubility of Li in remaining L phase and $\alpha_{\text{Al}}$ leads to precipitation of metastable $\delta'$ inside the grains of $\alpha_{\text{Al}}$. With temperature decrease, stable $\delta$ phase nucleates at the grain boundaries of $\alpha_{\text{Al}}$. Stable $\delta$ phase grows on the account of previously precipitated $\alpha_{\text{Al}}$ and metastable $\delta'$ phase and leads to formation of PFZ near the grain boundaries. Precipitation of T phase widens the PFZ. Solidification sequence ends with precipitation of $\beta$ phase at the grain boundaries.

Metallographic analysis of the sample, after compression testing, revealed low energy layering fracture as a failure along the grain boundaries. Interaction between $\delta'$ phase and dislocations caused textured development in the affected area. Precipitation of $\delta$ and $\beta$ phase weakens the grain boundaries. Segregations of Mg at the grain boundaries led to the solid solution strengthening and ductility decrease.

The conducted investigations indicated that Mg has more pronounced effect on low energy delamination fracture development by:

- Reducing solubility of Li in L phase and $\alpha_{\text{Al}}$
- Maximizing precipitation of hardening $\delta'$ phase particle
- Precipitation of ternary T phase and widening PFZ
- Precipitation of irregular $\beta$ phase particles at the grain boundaries
- Solid solution hardening
